Abstract: The cold tongue mode (CTM), which represents the out-of-phase relationship in sea surface temperature anomaly (SSTA) variability between the Pacific cold tongue region and elsewhere in the tropical Pacific, shows a long-term cooling trend in the eastern equatorial Pacific. In this study, we investigate how well the CTM is reproduced in historical simulations generated by the 20 models considered in Phase 5 of the Coupled Model Intercomparison Project (CMIP5). Qualitatively, all 20 models roughly capture the cooling SSTA associated with the CTM. However, a quantitative assessment (i.e., Taylor diagrams and the ratio of the trend between the simulations and observations) shows that only five of these 20 models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M) can reproduce with useful accuracy the spatial pattern and long-term trend of the CTM. We find that these five models generally simulate the main ocean dynamical process associated with the CTM. That is, these models adequately capture the long-term cooling trend in the vertical advection of the anomalous temperature by the mean upwelling. We conclude that the performance of these CMIP5 models, with respect to simulations of the long-term cooling trend associated with the vertical advection, and the related long-term decreasing trend of the vertical gradient of the oceanic temperature anomaly, can play an important role in successful reproduction of the CTM.

Keywords: tropical Pacific; La Niña-like; cold tongue mode; ocean dynamical process; CMIP5

1. Introduction

In recent years, El Niño-Southern Oscillation (ENSO) diversity, representing differences in the sea surface temperature anomalies (SSTA) of ENSO events, has been a topic of great interest (e.g., Karnauskas, 2013; Ren HL and Jin FF, 2013; Ren HL et al., 2013, 2016a; Zhang WJ et al., 2013, 2014; Zheng F et al., 2014, 2016; Capotondi et al., 2015; Zheng F and Yu JY, 2017). Many studies have pointed out that the tropical Pacific background state makes an important contribution to ENSO diversity under global warming (Ashok et al., 2007; Yeh et al., 2009; Collins et al., 2010; Duan WS et al., 2014; Li Y et al., 2017; Lemmon and Karnauskas, 2018). Numerous studies have reported that the tropical Pacific background state is similar to a La Niña-like pattern (i.e., greater warming in the west than the east) and that it plays an important role in ENSO diversity (Duan WS et al., 2014; Li Y et al., 2017; Jiang N and Zhu CW, 2018; Lemmon and Karnauskas, 2018).

Although there is disagreement about the relationship between the long-term trend of tropical Pacific and global warming (Collins et al., 2010), the La Niña-like pattern has been confirmed by many observations. For example, Li Y et al. (2017) reported that the subsurface temperature of the eastern equatorial Pacific is cooler than that of the western equatorial Pacific; Karnauskas et al. (2009) and Coats and Karnauskas (2017) pointed out that many datasets indicate a strengthening of the equatorial Pacific zonal SST gradient. Meanwhile, the equatorial undercurrent and subtropical cells associated with the La Niña-like pattern have been demonstrated to be accelerating (Drenkard and Karnauskas, 2014; Yang CX et al., 2014; Coats and Karnauskas, 2018). Some atmospheric evidence also supports the La Niña-like pattern, such as the strengthening of Walker circulation and trades (L'Heureux et al., 2013; Li Y et al., 2019). These results indicate that the La Niña-like condition plays a dominant role in the tropical Pacific under global warming (Cane et al., 1997).

Many studies have demonstrated that the second EOF mode of the tropical Pacific can present a La Niña-like pattern under global warming (Zhang WJ et al., 2010; Li JP et al., 2013; Duan WS et al., 2014; Li Y et al., 2015, 2017, 2019; Lemmon and Karnauskas, 2019).

As shown in Figure 1, the second EOF mode represents an out-of-phase relationship in SSTA variability between the Pacific cold tongue region and the rest of the tropical Pacific. Its spatial pattern is consistent with the La Niña-like pattern (Fig. 5 in Solomon and Newman, 2012), and its normalized principal components (NPC2) show a strong long-term trend. This means that there is a cooling cold tongue region under global warming. In addition, it can be seen from Figure 1 that ENSO is identified by the first EOF mode, with strong interannual variability (Deser et al., 2009; Compo and Sardeshmukh, 2010; Zhang WJ et al., 2010).

Figure 1. The spatial patterns and corresponding normalized PCs of the first two leading EOF modes of the tropical Pacific SSTA (°C) for the HadISST1 dataset.

Following previous studies (Zhang WJ et al., 2010; Li JP et al., 2013; Li Y et al., 2015, 2017, 2019; Jiang N and Zhu CW, 2018), the second EOF mode is referred to as the cold tongue mode (CTM). Li Y et al. (2015) emphasized that "the long-term trend of the CTM is dominated by the vertical advection of the anomalous temperature by the mean upwelling ($-\bar{w}\partial T'/\partial z$)". Although net heat flux and other ocean dynamical processes also contribute to the CTM, the effect of the $-\bar{w}\partial T'/\partial z$ term is the main ocean dynamical process in the CTM.

It is noted that the CTM has been identified not only in observations, but also in climate models. Zhang WJ et al. (2010) pointed out that the CTM is accurately simulated in the 20th century run of some Phase 3 models in the Coupled Model Intercomparison Project (CMIP3). The current Phase 5 CMIP (CMIP5) models have higher spatial resolution relative to those in CMIP3 (Taylor et al., 2012). In addition, the CMIP5 models have improved the simulation of climate variability; some are able to capture important climate phenomena in the Pacific, for example ENSO (Kim and Yu JY, 2012; Kug et al., 2012; Zhang WJ and Jin FF, 2012; Bellenger et al., 2014; Ren HL et al., 2016b; Lin RP et al., 2018), Pacific Decadal Oscillation (PDO) (Newman et al., 2016), and the La Niña-like pattern (Funk and Hoell, 2015). However, no research has been devoted to investigating the CTM in the CMIP5 simulations. Consequently, in this study we aim to address two main issues: How well do the CMIP5 models reproduce the CTM pattern and its long-term trend? If some models reproduce the CTM well, how well do these models reproduce the main ocean dynamical process associated with the CTM?

The remainder of this paper is organized as follow. Section 2 introduces the data and methods used in this study. An analysis of the performance of the models in reproducing the historical CTM is presented in Section 3. The performance of the models in reproducing the main ocean dynamical process associated with the CTM is discussed in Section 4. Finally, discussion and conclusions are presented in Section 5.

2. Data and Methods

2.1 Data

We used monthly SST from UK Met Office's Hadley Centre Sea Ice and SST version 1 (HadISST1) dataset (Rayner et al., 2003). We analyzed simulations from the 20 models that participated in CMIP5. The model output and information, including their developing centers and horizontal resolutions, are listed in Table 1. To evaluate the performance of the models in reproducing the CTM, we used monthly output over the period 1870–2004 from historical simulations (r1i1p1), which were forced by observed atmospheric composition changes from natural and anthropogenic sources (Taylor et al., 2012). As the ocean component of most models used a tripolar global grid, the modeled outputs of ocean variables (SST, ocean subsurface temperature, and upwelling) were interpolated onto a common rectangular grid of 1.0° × 1.0° prior to further calculations. Note that the mean seasonal cycle of all datasets from 1961 to 1990 was removed and that our results are not sensitive to the choices of mean seasonal cycle.

2.2 Methods

To avoid the impact of outliers on trend estimation, trends were calculated as the Theil–Sen median slope (Sen, 1968; Theil, 1992) and tested for statistical significance using the Mann–Kendall test. Note that the Theil–Sen trend estimation method is measured by the median of slopes between all pairs and that it was determined using the following equation:

$$\text{trend} = \text{Median}\left(\frac{x_i - x_j}{i - j}\right),$$
$$\forall j < i, 1 \leqslant j < i \leqslant N$$

where trend is the Theil–Sen trend, x_i and x_j are one data pair, and N is the sample size.

In addition, we used the partial correlation coefficient (PR) to detect the relationship between each pair of variables after excluding the effect of the third variable. Moreover, linear regression was used to remove the specific signal. Note that the PR and removal related to linear regression can exclude only linear components but not nonlinear interactions (Zheng F et al., 2015).

3. Performance of CMIP5 Models in Reproducing the CTM

3.1 ENSO Mode Simulated by CMIP5 Models

As mentioned above, the first EOF mode over the tropical Pacific represents the ENSO mode (Deser et al., 2009; Compo and Sardeshmukh, 2010; Zhang WJ et al., 2010), and the second EOF mode depicts the CTM (Zhang WJ et al., 2010; Li JP et al., 2013; Duan WS et al., 2014; Li Y et al., 2015, 2017). ENSO represents the interannual variability of ocean dynamical processes (Collins et al., 2010), while the CTM is dominated by the long-term change of ocean dynamical processes (Zhang WJ et al., 2010; Li JP et al., 2013; Li Y et al., 2015, 2017). It is suggested that the simulation of ENSO may play an important role in reproducing the CTM (Zhang et al., 2010). Therefore, we first assess the ENSO mode before examining the performance of CMIP5 models in reproducing the CTM. This approach is similar to that of Zhang WJ et al. (2010).

Figure 2 shows the first EOF modes of SSTA over the tropical Pacific and their corresponding NPC1 time series that are simulated by each of the 20 CMIP5 models. Qualitatively, it can be seen from Figure 2 that the spatial pattern of the ENSO mode is not captured by six of the models (i.e., BCC-CSM1-1-M, CanESM2, CCSM4, GISS-E2-H, IPSL-CM5A-LR, and MPI-ESM-P). This is because these six models show a warming SSTA across almost the whole tropical Pacific, and their time series exhibit no significant interannual variability and are dominated by a rising trend in SSTA (Figure 2). In particular, for four of the models (i.e., CanESM2, GISS-E2-H, IPSL-CM5A-LR, and MPI-ESM-P), their time series almost correspond to a strong warming trend (Figure 2). According to previous research (Zhang WJ et al., 2010), the most plausible cause of this res-
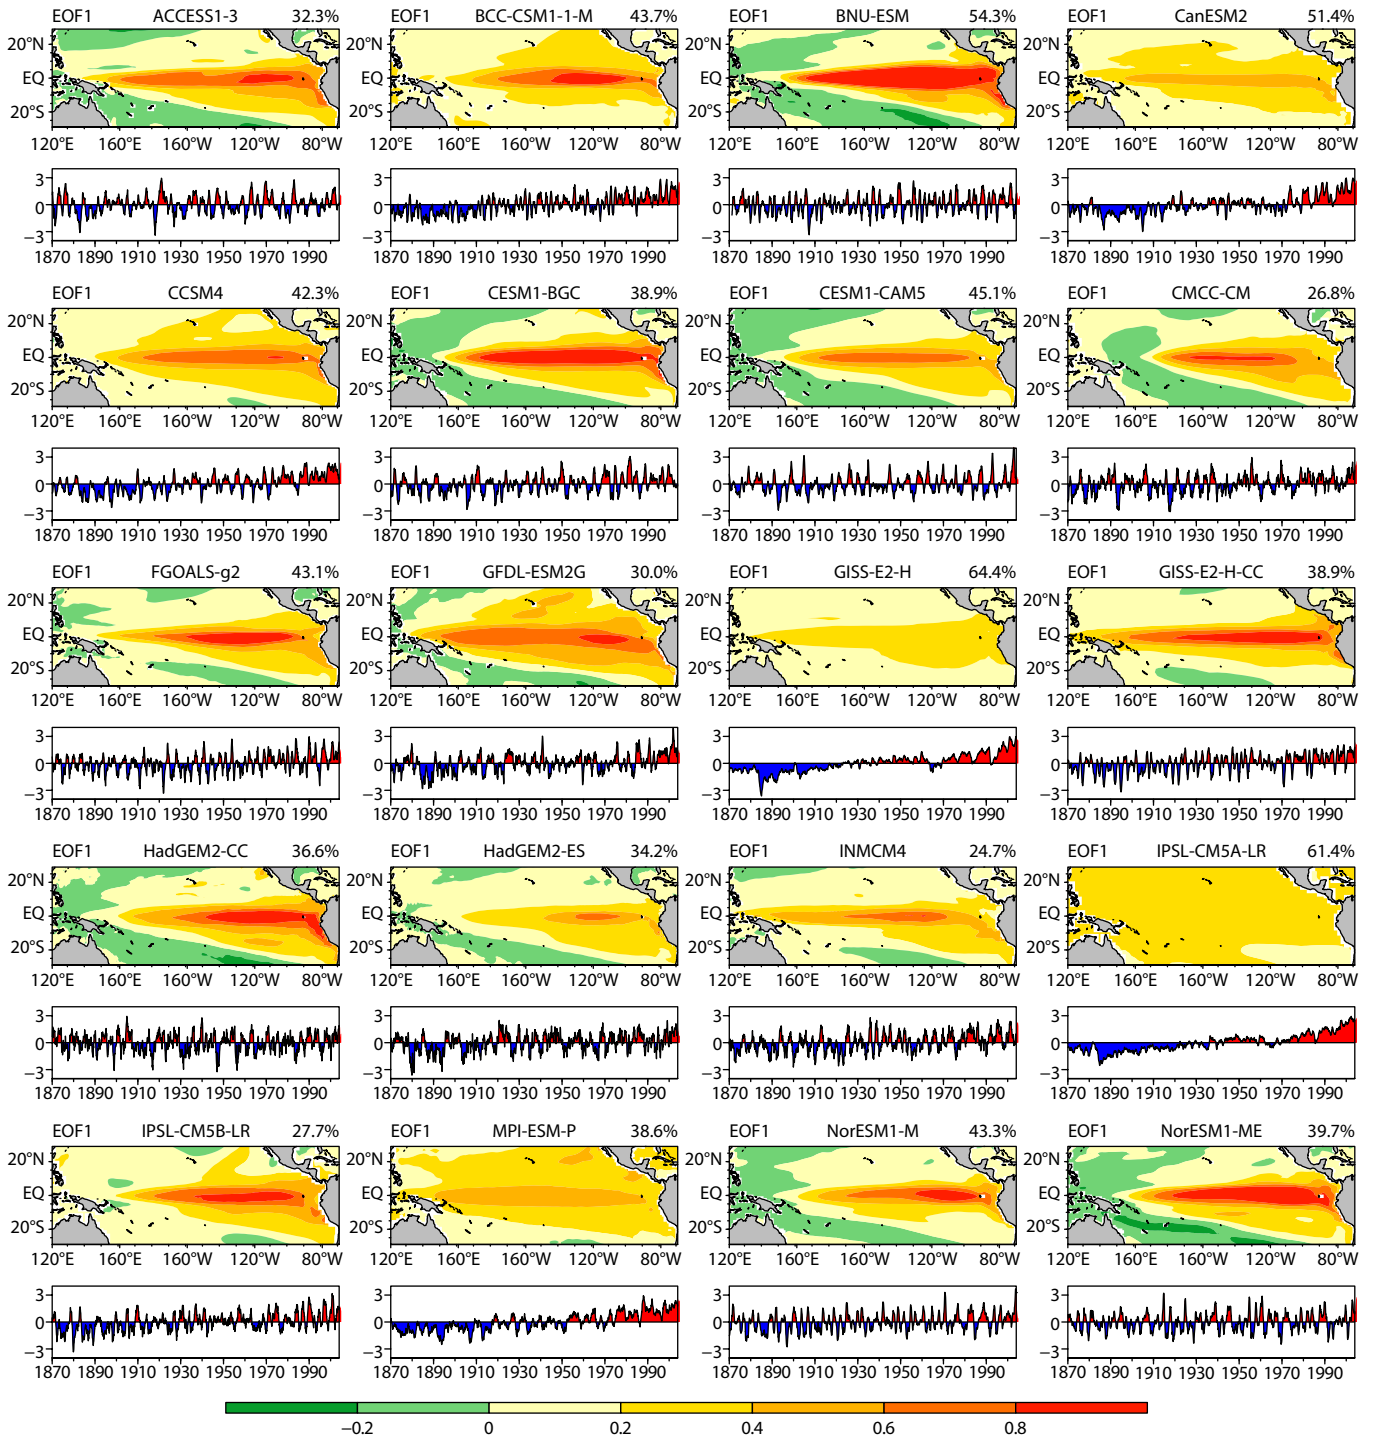

Figure 2. The first EOF modes in SSTA (°C) over the tropical Pacific and their corresponding NPC1 time series for the historical simulations. The model names and variances are shown above each EOF mode.

ult is that the interannual signal of the ENSO mode is hidden by global warming.

To quantitatively examine the accordance between the CMIP5 models and the observations, a pair of Taylor diagrams (Taylor, 2001) is used to compare the performance of the models based on the spatial pattern of the ENSO mode. For the six models named above, the corresponding ratios of the standard deviation of the modeled and observed ENSO patterns are less than 0.75

(Figure 3a). Using root-mean-square (RMS) differences between the simulations and the observations, shown as the distance between the model point and the "REF" point in the Taylor diagram, the distances obtained for these six models are approximately greater than 0.5 (Figure 3a). This supports the conclusion that these six models perform less well in reproducing the observed ENSO pattern.

Aside from the above six models, three models (i.e., BNU-ESM, GF-

Figure 3. Taylor diagram of the (a) ENSO pattern and (b) CTM pattern. Each numbered dot represents a single model. The term "REF" on the horizontal axis indicates the reference point. Black solid lines and dashed arcs indicate the correlation coefficient and ratio of standard deviations, respectively, between modeled and observed (HadISST1) ENSO/CTM pattern. Black dotted arcs show the centered root mean square difference that is equal to the radial distance from the reference point.

DL-ESM2G, and GISS-E2-H-CC) tend towards strong interannual variability in the western equatorial Pacific (Figure 2). Correspondingly, the RMS differences of these six models are approximately larger than 0.5 (Figure 3a). In particular, BNU-ESM generates an RMS difference of more than 1.0 (Figure 3a). Meanwhile, another two models (i.e., HadGEM2-ES and INMCM4) underestimate the amplitude of the ENSO mode (Figure 2). This can be seen from the ratios of the standard deviation of the modeled and observed ENSO patterns, whose values are just about 0.5 (Figure 3a).

Another important aspect of the behavior of ENSO is its spectral characteristics; i.e., ENSO shows an interannual variability. Here, we use the continuous power spectrum to examine periodicity of ENSO mode in the observation and performance of the CMIP5 models in reproducing the spectral structure of the ENSO mode. The NPC1 of ENSO mode in the observation shows a significant periodicity of 2–4 years. In summary, most of the models capture the observed spectral peak at 2–4 years (Figure 4), except for the six models mentioned above (i.e., BCC-CSM1-1-M, CanESM2, CCSM4, GISS-E2-H, IPSL-CM5A-LR, and MPI-ESM-P), which all have spectral peaks at very low frequency. This corresponds to the strong long-term trend of the time series in these six models. It further suggests that the interannual signal of these six models is masked by global warming.

Overall, 11 models (i.e., BCC-CSM1-1-M, BNU-ESM, CanESM2, CCSM4, GFDL-ESM2G, GISS-E2-H, GISS-E2-H-CC, HadGEM2-ES, INMCM4, IPSL-CM5A-LR, and MPI-ESM-P) are not able accurately to capture the spatial or temporal characteristic of the ENSO mode (Figures 3a and 4). The remaining nine models (i.e., ACCESS1-3,

CESM1-BGC, CESM1-CAM5, CMCC-CM, FGOALS-g2, HadGEM2-CC, IPSL-CM5B-LR, NorESM1-M, and NorESM1-ME) perform well in reproducing both the observed spatial pattern and the interannual variations of the ENSO mode. It can be seen from Figure 3a that the distances between the points associated with these nine models and the "REF" point are generally smaller than those of the other 11 models. Also, these nine models exhibit peaks over interannual scales of about 2–4 years.

3.2 CTM Simulated by CMIP5 Models
As discussed above, we first analyze the performance of the CMIP5 models in reproducing the ENSO mode. Next, we consider how well the CMIP5 models reproduce the spatial and temporal characteristics of the CTM. We know that in nature the CTM represents an out-of-phase relationship of SSTA variability between the Pacific cold tongue region and elsewhere in the tropical Pacific, and that the time series of the CTM exhibits a strong long-term trend (Figure 1). Thus, in the following, we use the Taylor diagram to evaluate the spatial pattern of the modeled CTM, and use the ratio of trends to make a comparison between the modeled and observed time series of the CTM.

Figure 5 shows the second EOF modes in SSTA over the tropical Pacific and their NPC2 time series. Most of the models are able to simulate the cooling SSTA in the eastern equatorial Pacific associated with the positive CTM well (Figure 5). However, compared with Taylor diagram analysis of the ENSO mode (Figure 3a), the spatial correlation coefficients in Figure 3b are overall lower (Figure 3b), and the distances between the model points and the
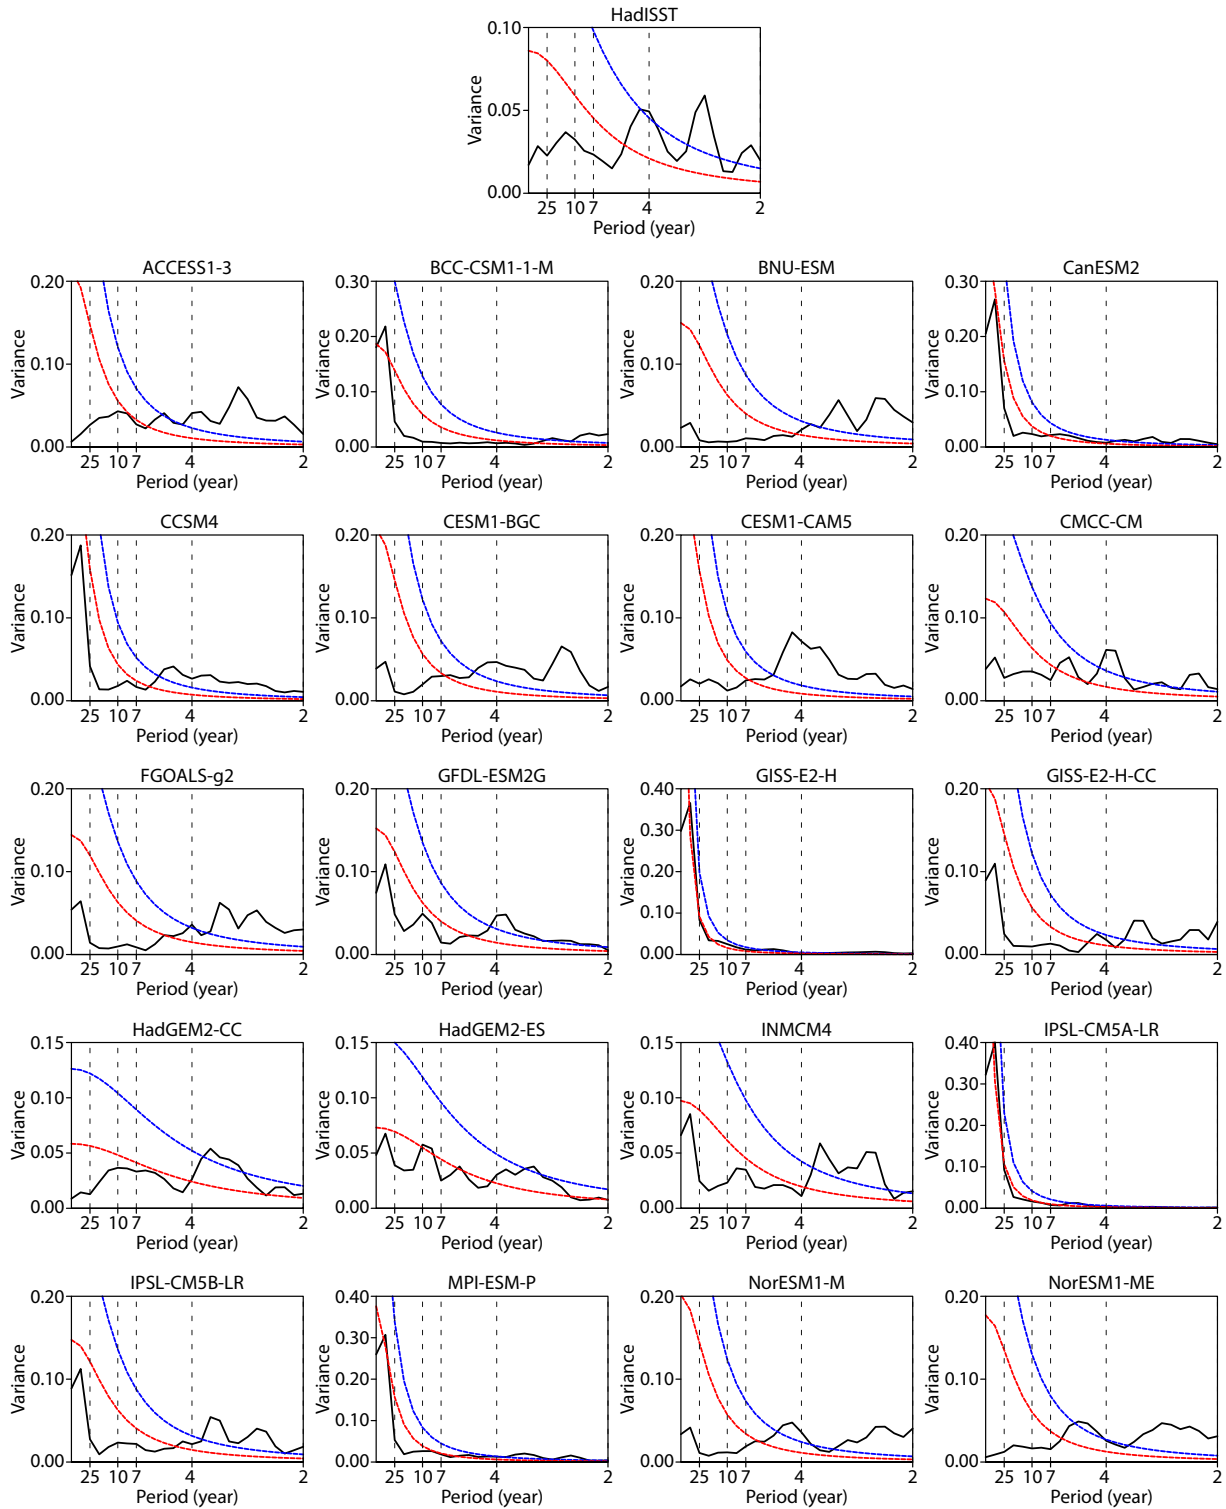

Figure 4. Power spectrum of the NPC1 derived from the HadISST1 dataset and individual CMIP5 models. The blue and red dashed lines show the 95% confidence level and the reference red noise spectra, respectively.

"REF" point (Figure 3b) are typically greater. This implies that the CMIP5 models generally provide a better simulation of the ENSO mode than of the CTM. Interestingly, eight of the models (i.e., BCC-CSM1-1-M, BNU-ESM, CCSM4, GFDL-ESM2G, GISS-E2-H, HadGEM2-ES, INMCM4, and MPI-ESM-P) mentioned above, which are not able accurately to simulate the spatial or temporal charac-

teristic of the ENSO mode, are also unable to capture realistically the spatial features of the CTM. We note that these eight models have weaker spatial correlation coefficients, smaller ratios of the standard deviation, or are further from the "REF" point in comparison with the other models (Figure 3b).

Considering the simulation of the temporal features of the CTM,

Figure 5. As Figure 2, but for the second EOF mode and its corresponding NPC2 time series.

we use the ratio of the simulated and observed trends of NPC2 to assess the performance of the CMIP5 models in reproducing the long-term trends in the CTM. Quantitatively, there are eight models (i.e., ACCESS1-3, CanESM2, GFDL-ESM2G, GISS-E2-H, HadGEM2-CC, IPSL-CM5A-LR, MPI-ESM-P, and NorESM1-ME) whose ratios of trends are relatively weak compared with the other models (Figure 6). For four of these models in particular (i.e., ACCESS1-3, GISS-E2-H, HadGEM2-CC, and IPSL-CM5A-LR), their NPC2 time series are almost dominated by the interannual signal (Figure 5). This suggests that the CTM simulated by these eight models tends to have

a stronger interannual signal than that seen in the observations. In addition, of these eight models mentioned above, we also note that five (i.e., CanESM2, GFDL-ESM2G, GISS-E2-H, IPSL-CM5A-LR, and MPI-ESM-P) do not accurately reproduce the spatial or temporal characteristics of the ENSO mode. Except for these eight models, the rest of the models yield ratios of trends between the simulated and observed NPC2 time series that are generally located within a band about 0.2 wide centered on 1.0 (Figure 6). This indicates that the 10 models in the pink rectangle (Figure 6) are able to capture the observed long-term trend of the CTM. In addi-

**Li Y and Chen Q L et al.: The CTM in CMIP5**

Figure 6. The ratio of the trends of the NPC2 between the historical simulations and the observations. The models in the pink rectangle are those that reasonably reproduce the observed long-term trend of the CTM when compared with the other models. The red dots indicate the numbers of those better modes. The HadISST1 dataset is used for reference.

tion, we note that in the CESM1-BGC and GISS-E2-H-CC models the long term trends are relatively strong compared with the observations (Figures 5 and 6).

Overall, 15 models (i.e., ACCESS1-3, BCC-CSM1-1-M, BNU-ESM, CanESM2, CCSM4, CESM1-BGC, GFDL-ESM2G, GISS-E2-H, GISS-E2-H-CC, HadGEM2-CC, HadGEM2-ES, INMCM4, IPSL-CM5A-LR, MPI-ESM-P, and NorESM1-ME) are unable to capture satisfactorily the spatial or temporal characteristic of the CTM (Figures 3b and 6). Compared with the capability, mentioned above, of the CMIP5 models in capturing the ENSO mode, our analysis suggests that if a model is not able to reproduce ENSO, then it is likely also to be unable to simulate the CTM usefully. This finding supports the suggestion of Zhang WJ et al. (2010), who emphasized that the reproduction of the CTM depends on the simulation ability of ENSO in CMIP3 models. Finally, we find that five models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M) yield superior results, reproducing realistic ENSO features and observed spatial characteristic and long-term trends associated with the CTM. Why the CTM is better simulated by these five models will be discussed in the following section.

4. Performance of CMIP5 Models in Reproducing the Main Ocean Dynamical Process Associated with the CTM

4.1 Main Ocean Dynamical Process Associated with the CTM

Li Y et al. (2015, 2017) used the heat budget equation to show that "the cooling associated with the vertical advection of the anomalous temperature by the mean upwelling ($-\bar{w}\partial T'/\partial z$) plays a dominant role in the long-term trend of the CTM, and this is consistent with the results of DiNezio et al. (2009)". Since the CTM is well-simulated in the five models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M), we expect the cooling trend of the $-\bar{w}\partial T'/\partial z$ term to be captured by these five models.

The bottom panels in Figure 7 show a normalized time series of the $-\bar{w}\partial T'/\partial z$ term in the eastern equatorial Pacific. It should be noted that the averaged area (2°S–2°N, 140°W–80°W, and 0–60 m) of the $-\bar{w}\partial T'/\partial z$ term is the same as that of Li Y et al. (2015), who analyzed the cooling trend of the $-\bar{w}\partial T'/\partial z$ term in the observations. Although the time series of the $-\bar{w}\partial T'/\partial z$ term in the five models exhibit a strong interannual variability (Figure 7), they all follow a cooling trend, except in that of CESM1-CAM5 (Table 2). Note also that these trends in the five models exceed the 95% confidence level (Table 2). In addition, Compo and Sardeshmukh (2010) suggested that ENSO can be treated as noise when analyzing the long-term trend in the tropical Pacific. This indicates that ENSO may hinder our understanding of the long-term trend of the $-\bar{w}\partial T'/\partial z$ term in CESM1-CAM5. For this reason, we first remove the ENSO signal and then perform a trend analysis on the time series of the $-\bar{w}\partial T'/\partial z$ term generated by the five models. To remove the ENSO signal, the raw time series of the $-\bar{w}\partial T'/\partial z$ term is regressed onto the monthly Niño 3 index, and the obtained result is then subtracted from the raw time series of the $-\bar{w}\partial T'/\partial z$ term. After removal of the ENSO signal, the trend of the $-\bar{w}\partial T'/\partial z$ term in CESM1-CAM5 tends towards cooling (Table 2), although this trend is statistically insignificant. For the other four models, the cooling trends of the $-\bar{w}\partial T'/\partial z$ term without the ENSO signal are stronger than the raw trends (Table 2). These results suggest that the cooling trend of the $-\bar{w}\partial T'/\partial z$ term is overall captured by these five models.

Despite there being a statistically insignificant trend of the $-\bar{w}\partial T'/\partial z$ term time series in CESM1-CAM5, the partial correlation coefficients (PRs) without the ENSO signal (Niño 3 index) between the tropical Pacific temperature anomalies (averaged over 0–60 m) and the $-\bar{w}\partial T'/\partial z$ term time series correspond to strong negative correlation (multiplied by –1.0) in the eastern equatorial Pacific, where the cooling $-\bar{w}\partial T'/\partial z$ term is associated with the cooling temperature anomalies (Figure 7a). For the other four models, their PRs also correspond to strong negative correlation in the eastern equatorial Pacific. These spatial patterns of PR in the five
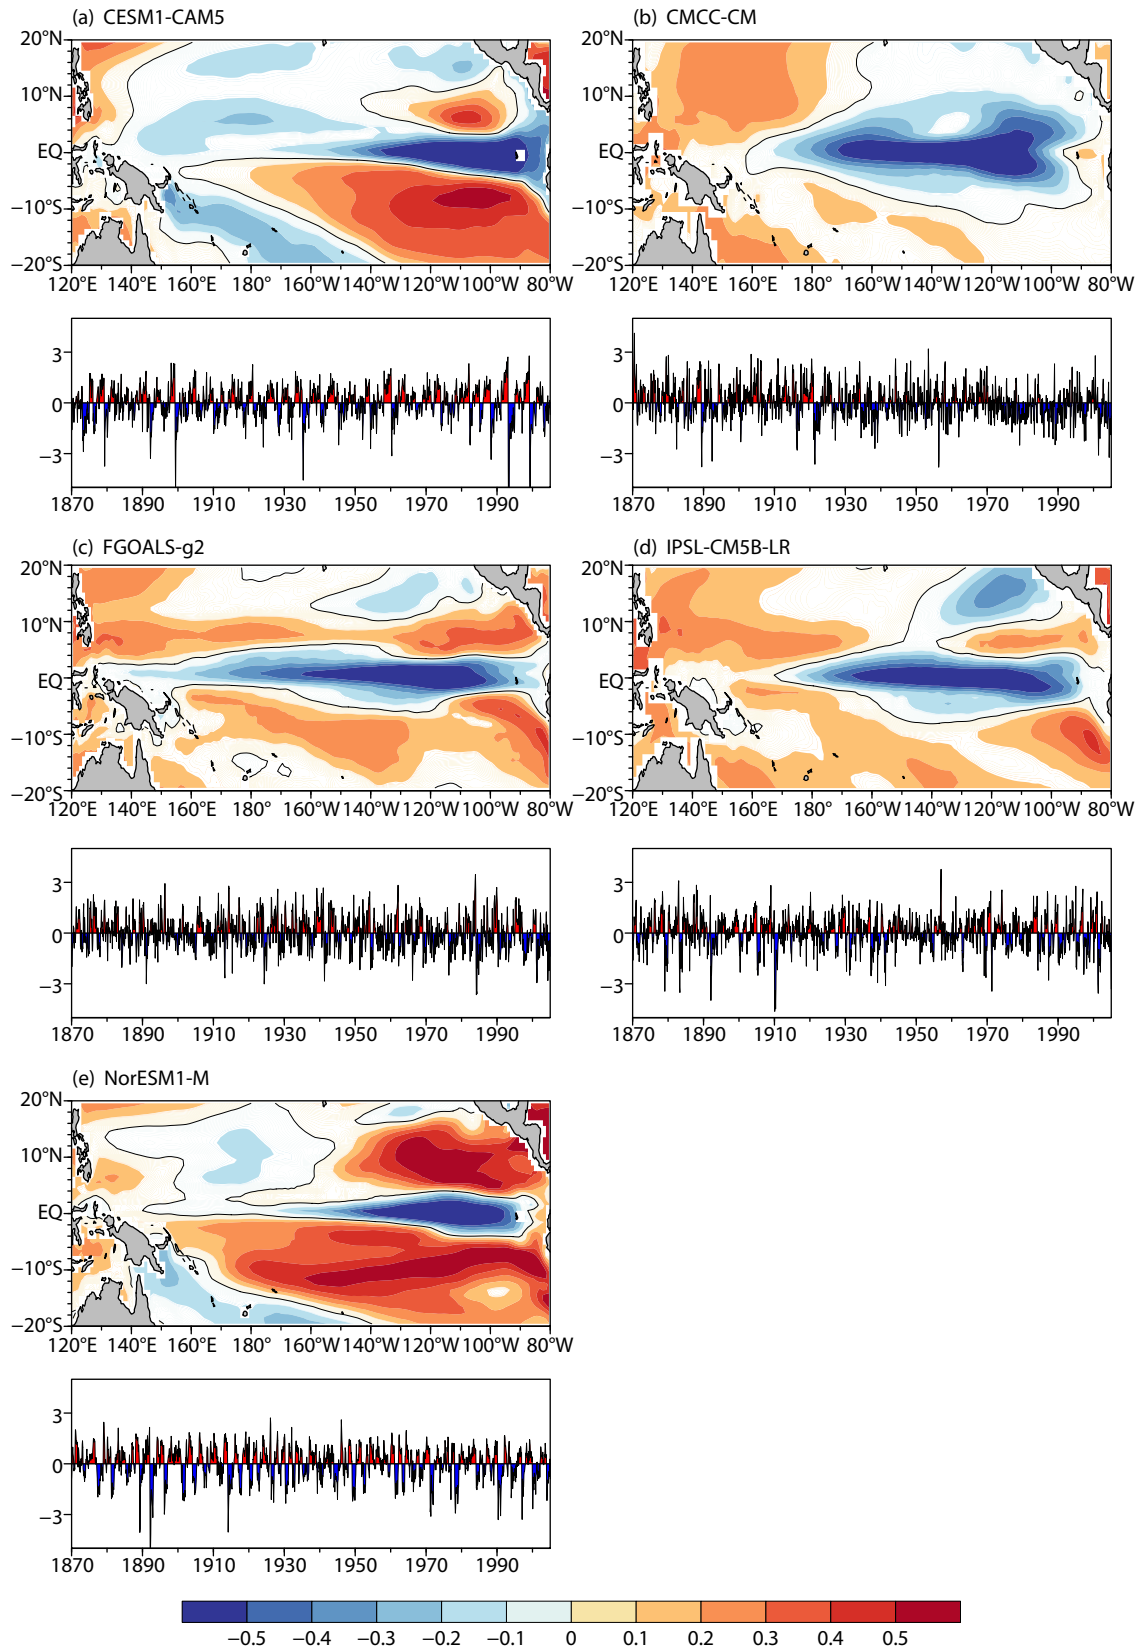

Figure 7. Top panels of (a)–(e) are the PR (after removal of ENSO) between the tropical Pacific oceanic temperature (0–60 m) and the indices of the vertical advection of the anomalous temperature by the mean upwelling in five models. The bottom panels of (a)–(e) are the corresponding normalized time series of the indices. These indices are calculated over 2°S–2°N, 140°W–80°W, and 0–60 m. The historical simulations are from CESM-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M. Shading indicates statistical significance at the 99.9% confidence level, and the thin black contour denotes the zero line. To allow a direct comparison, the PR patterns in (a)–(e) are multiplied by –1.0.

models (Figure 7) are similar to the spatial pattern of the positive CTM (Figure 1), which shows the cooling SSTA in the tropical Pacific cold tongue region. The above results indicate that the five models generally simulate the main ocean dynamical process associated with the CTM.

The analysis above motivated us to examine further why these five models are able to capture the main ocean dynamical process associated with the CTM. Li Y et al. (2015, 2017) emphasized that "the cooling term $-\bar{w}\partial T'/\partial z$ is controlled by the decreasing vertical gradient of temperature anomalies ($\partial T'/\partial z$)". Thus, the question becomes How well do the five models reproduce the decreasing trend of the $\partial T'/\partial z$ term? To address this issue, in the following section we will investigate the trend of the $\partial T'/\partial z$ term and its associated sea temperature pattern in the five models.

4.2 Vertical Temperature Gradient in the Eastern Equatorial Pacific

Figure 8 shows, for the five models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M), their normalized time series of the $\partial T'/\partial z$ term and their corresponding PR patterns. After removal of the ENSO signal, the PRs between the tropical Pacific temperature anomalies and the $\partial T'/\partial z$ term all tend towards a significantly strong negative correlation (multiplied by −1.0) in the eastern equatorial Pacific, where the decreasing $\partial T'/\partial z$ term is associated with the cooling temperature anomalies (Figure 8). Meanwhile, in four of the five models (i.e., except for CESM1-CAM5; Table 2), the time series of the $\partial T'/\partial z$ term show a decreasing trend. After excluding the interference related to the ENSO signal, the time series of the $\partial T'/\partial z$ term also follows a decreasing trend in CESM1-CAM5, although this trend is statistically insignificant (Table 2). For the CESM1-CAM5 simulation without the ENSO signal, this insignificant decreasing trend of the $\partial T'/\partial z$ term could induce the weak cooling trend of the $-\bar{w}\partial T'/\partial z$ term in the eastern equatorial Pacific (Table 2). In addition, the decreasing trends of the $\partial T'/\partial z$ term without the ENSO signal are stronger relative to their raw trends in all five models (Table 2). These simulated results are similar to the observed results of Li Y et al. (2017). Overall, these results suggest that the five models generally reproduce the decreasing $\partial T'/\partial z$ term in the eastern equatorial Pacific.

To further clarify the decreasing $\partial T'/\partial z$ term in the eastern equatorial Pacific, the trends of the $\partial T'/\partial z$ term are calculated from the

surface to thermocline (about 60 m). As shown in Figure 9, the raw trends of the $\partial T'/\partial z$ term from the surface to thermocline are decreasing in all five models except CESM1-CAM5. After removal of the ENSO signal, the decreasing trends in these five models are generally stronger than the raw trends from the surface to 40 m (Figure 9). Note that the trends in the $\partial T'/\partial z$ term without the ENSO signal are insignificant in CESM1-CAM5, although they do decrease above 50 m. Aside from CESM1-CAM5, the decreasing trends without the ENSO signal above 40 m are statistically significant (Figure 9). These results are consistent with the above analysis that shows the long-term trend of the time series of the $\partial T'/\partial z$ term without the ENSO signal (Table 2).

We also analyze the long-term trends of the subsurface temperature of the eastern equatorial Pacific in the five models (Figure 10). The raw trends above thermocline in these five models are generally warming (Figure 10). However, the raw trends of sea temperature in four of the models (i.e., CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M in Figure 10) are that warming decreases with increased depth. This pattern induces the decreasing trend of the $\partial T'/\partial z$ term above the thermocline in these four models (Figure 9). Interestingly, when the ENSO signal is removed, the subsurface temperature of the eastern equatorial Pacific in all five models shows a cooling trend (Figure 10). This simulated result is consistent with the observed result of Li Y et al. (2017), who found a cooling trend of subsurface temperature in the eastern equatorial Pacific. Moreover, the trends above 40 m without the ENSO signal are statistically significant and are cooling at all depths in all five models (Figure 10), and contribute to the decreasing trend in the $\partial T'/\partial z$ term without the ENSO signal above 40 m (Figure 9). Overall, these results indicate that the five models could capture the main ocean dynamical process associated with the CTM, namely, the decreasing trend of the $\partial T'/\partial z$ term and the cooling trend of the $-\bar{w}\partial T'/\partial z$ term.

5. Discussion and Conclusions

This study used historical simulations generated by 20 CMIP5 models to test their ability to simulate the CTM. Using Taylor diagrams, the power spectra, and the ratio of the trend in normalized principal components (NPC2) between the model simulations and the observations, we evaluated the spatial and temporal characteristics of the ENSO mode and CTM in these 20 models. In general, we find that models unable accurately to simulate the
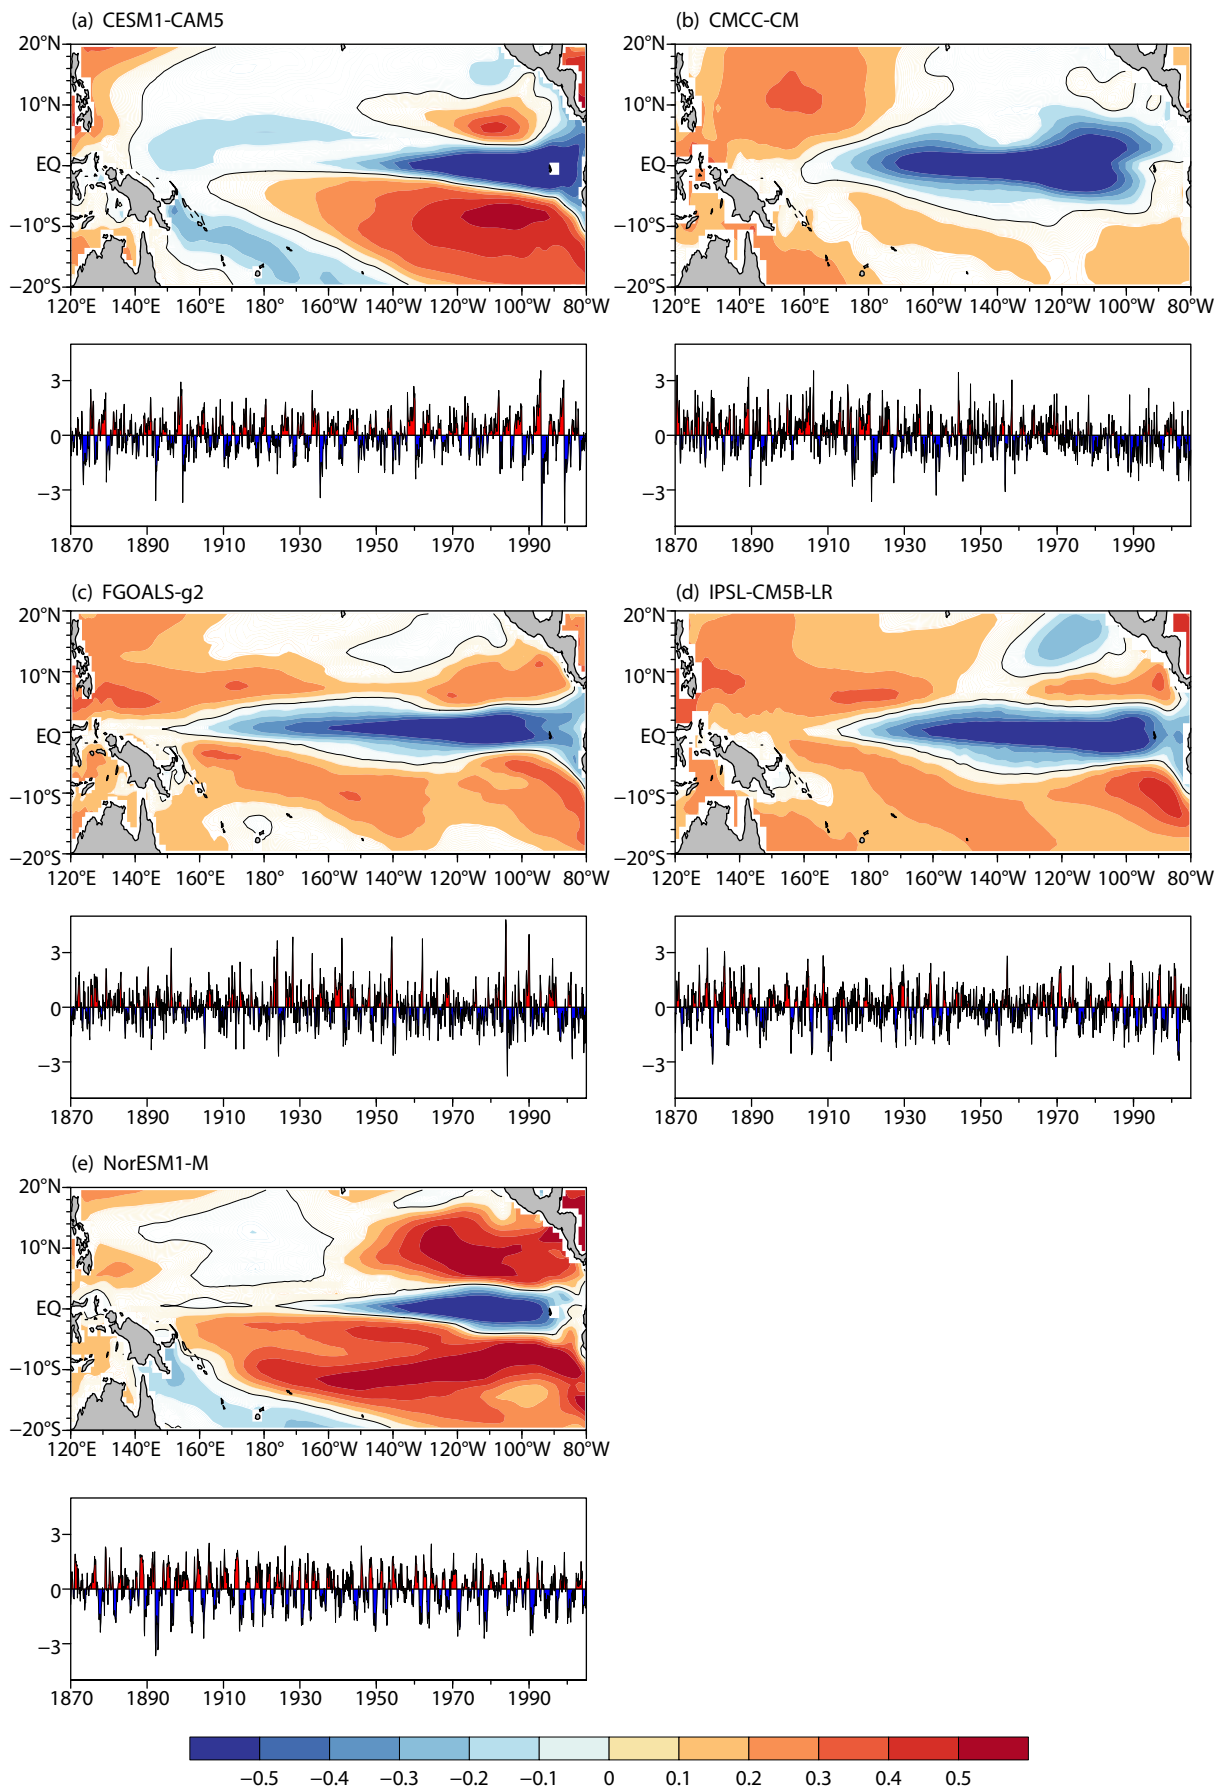

Figure 8. As Figure 7, but for the vertical temperature gradient. To allow a direct comparison, the PR patterns in (a)–(e) are multiplied by −1.0.
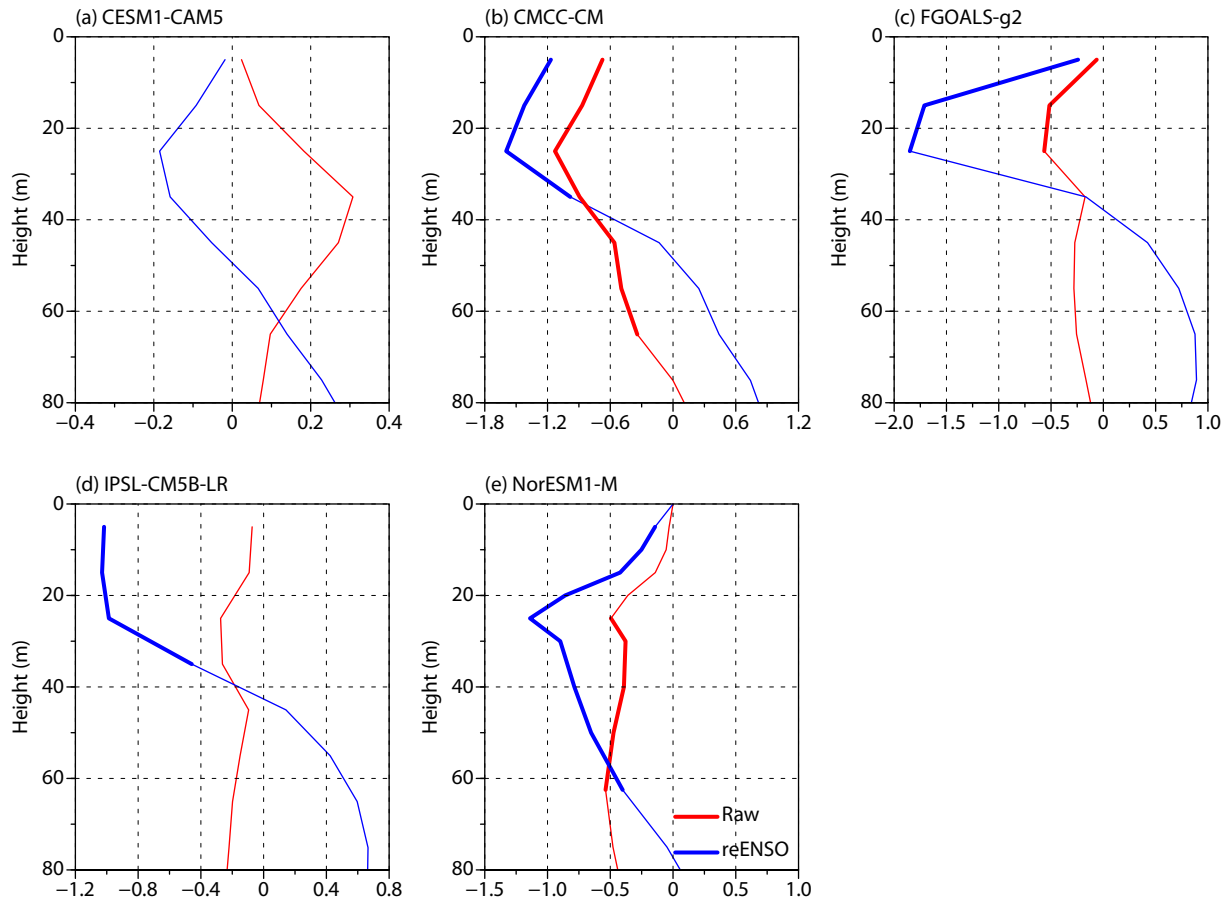

Li Y and Chen Q L et al.: The CTM in CMIP5

Figure 9. The trends (in 10^{-2} °C/m per 100 years) of vertical temperature gradient over the eastern equatorial Pacific (2°S–2°N, 140°W–80°W). The red and blue lines represent the raw trend and removed ENSO signal trend, respectively. Thicker lines indicate significant at the 95% confidence level (nonparametric Mann–Kendall test).

ENSO feature in the EOF1 mode of the tropical Pacific are also unable to reproduce usefully the observed spatial pattern and long-term trend associated with the CTM that appears in EOF2. Note that eleven of the models (i.e., BCC-CSM1-1-M, BNU-ESM, CanESM2, CCSM4, GFDL-ESM2G, GISS-E2-H, GISS-E2-H-CC, HadGEM2-ES, INMCM4, IPSL-CM5A-LR, and MPI-ESM-P) could not accurately simulate the spatial characteristic of ENSO and also could not reproduce the CTM well. Of the rest of the models, some are able to reproduce the ENSO features, but could not capture effectively the spatial characteristics or the long-term trend of the CTM. For instance, the models ACCESS1-3, HadGEM2-CC, and NorESM1-ME are unable to reproduce the spatial pattern of the CTM (Figure 3b), and the long-term trend of the CTM simulated by CESM1-BGC is too strong, compared with the observations (Figure 6). Finally, five models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M) are capable of capturing with reasonable accuracy the spatial pattern and long-term trend of the CTM. Note that other models are unable to simulate the CTM, which may be related to tropical biases in these CMIP5 models (Kug et al., 2012; Bellenger et al., 2014). In addition, based on the main ocean dynamical process associated with the CTM, the diversity among models in representing the mean upwelling of the eastern equatorial Pacific (Li G and Xie SP, 2012; Li Y et al., 2015) may induce the inter-model difference in the CTM (Figure 5).

Regarding the performance of CMIP5 models in reproducing the main ocean dynamical process associated with the CTM, we find that five models (i.e., CESM1-CAM5, CMCC-CM, FGOALS-g2, IPSL-CM5B-LR, and NorESM1-M) generally simulate the main ocean dynamical process associated with the CTM. In four of these five models (i.e., not in CESM1-CAM5; Table 2), the time series of the $-\bar{w}\partial T'/\partial z$ term in the eastern equatorial Pacific shows a cooling trend. After removal of the ENSO signal, however, all five models yield a cooling trend for the $-\bar{w}\partial T'/\partial z$ term in the eastern equatorial Pacific (Table 2). These results suggest that the five models generally reproduce the main ocean dynamical process associated with the CTM and thus capture the spatial pattern and long-term trend of the CTM.

The cooling trend of the $-\bar{w}\partial T'/\partial z$ term is controlled by the decreasing trend of the $\partial T'/\partial z$ term. We also find a decreasing trend in the $\partial T'/\partial z$ term after removing the ENSO signal in the eastern equatorial Pacific (Table 2). These decreasing trends are all significant, except for CESM1-CAM5 (Table 2). In CESM1-CAM5, the insignificant cooling trend of the $-\bar{w}\partial T'/\partial z$ term results from the insignificant decreasing trend of the $\partial T'/\partial z$ term (Table 2). Note that the decreasing $\partial T'/\partial z$ term is dominated by the change in subsurface temperature, which cools with increased depth in the eastern equatorial Pacific (Figure 10).

This study has briefly assessed the representation of the observed

Li Y and Chen Q L et al.: The CTM in CMIP5

Figure 10. As Figure 9, but for the trends (in °C per 100 years) of subsurface temperature.

CTM in the 20 CMIP5 models, and provides a new insight into the simulation of the dynamics of the tropical Pacific. However, the following questions remain. Why are some CMIP5 models unable to reasonably reproduce the CTM? How well do these models simulate the main ocean dynamical process associated with the CTM? Furthermore, although the CMIP5 models are demonstrably improved compared to the CMIP3 models, has there been corresponding improvement in their simulation of the CTM? If so, what is the cause of the improvement(s)? We will address these important questions in future studies.
